Project VYOM-SARATHI

Autonomous Constellation Management & Orbital Debris Avoidance System

Priyanshu Chauhan

National Space Hackathon 2026 Submission

Abstract

As Low Earth Orbit (LEO) becomes increasingly congested, traditional human-in-the-loop collision avoidance systems face severe scalability limits [1]. Project VYOM-SARATHI introduces a production-grade, fully autonomous Constellation Manager designed to mitigate the Kessler Syndrome [1]. This report details the architectural and mathematical foundations of the system, including a J_2-perturbed 4th-Order Runge-Kutta numerical integrator, an $\mathcal{O}(N \log N)$ `cKDTree` spatial index for rapid conjunction assessment, and an optimized HTML5 Canvas visualization dashboard. The system strictly adheres to all physical and communicative constraints, processing Kessler-level stress tests in under 20 milliseconds per simulation tick.

---

1 Core Backend Architecture

The Vyom-Sarathi backend is engineered for extreme throughput and low-latency execution to survive automated, high-frequency telemetry ingestion [1].

1.1 Stateless Memory Model & FastAPI

Built on Python 3.10+ using the FastAPI framework and Uvicorn (ASGI), the system ensures rapid asynchronous handling of JSON payloads. To completely eliminate database I/O bottlenecks during the simulation, the system utilizes an optimized, volatile in-memory dictionary (`ram_state`). It tracks the 6-DOF (Degree of Freedom) state vectors [1], fuel mass, and thruster cooldowns for every tracked object dynamically.

1.2 Numba JIT Compilation

Python's Global Interpreter Lock (GIL) and dynamic typing are bypassed using the `numba` library. All heavy astrodynamics mathematics are decorated with `@njit(fastmath=True, cache=True)`, compiling the Python functions directly into native C++ LLVM bytecode. To prevent "cold start" latency penalties during the initial API call, the server executes a pre-warming dummy calculation during the ASGI startup event, locking the integration speed to sub-10 milliseconds per tick.

2 Astrodynamics & Physics Engine

The simulation engine actively calculates complex orbital perturbations, discarding simplified Keplerian two-body assumptions [1]. All kinematic data is grounded in the Earth-Centered

Inertial (ECI) coordinate system [1].

2.1 Perturbation Models & Equations of Motion

Because Earth is an oblate spheroid, the acceleration function calculates the J_2 zonal harmonic tensor to accurately predict nodal regression and apsidal precession [1]. The equations of motion governing the constellation are given by:

$$\frac{d^2\vec{r}}{dt^2} = -\frac{\mu}{|\vec{r}|^3}\vec{r} + \vec{a}_{J_2} \tag{1}$$

Where the J_2 acceleration vector is defined as [1]:

$$\vec{a}_{J_2} = \frac{3}{2}\frac{J_2 \mu R_E^2}{|\vec{r}|^5}\begin{bmatrix} x\left(5\frac{z^2}{|\vec{r}|^2} - 1\right) \\ y\left(5\frac{z^2}{|\vec{r}|^2} - 1\right) \\ z\left(5\frac{z^2}{|\vec{r}|^2} - 3\right) \end{bmatrix} \tag{2}$$

2.2 Runge-Kutta 4th Order (RK4)

To propagate the orbits, the system utilizes a 4th-Order Runge-Kutta (RK4) integration scheme [1]. This provides the mathematical stability required for LEO over simple explicit Euler methods, ensuring maximum accuracy relative to the 10 km station-keeping bounding boxes [1] during unperturbed coasting phases.

2.3 Coordinate Frame Transformations

The engine calculates Greenwich Mean Sidereal Time (GMST) to perform precise rotations from the non-rotating ECI frame to the rotating Earth-Centered, Earth-Fixed (ECEF) frame. It subsequently utilizes spherical WGS84 approximations to rapidly project ECEF Cartesian coordinates into Geodetic Latitude, Longitude, and Altitude for frontend rendering.

3 Autonomous Collision Avoidance (Autopilot)

The Autopilot evaluates threats and calculates optimal evasion vectors without human intervention [1].

3.1 Spatial Indexing (`cKDTree`)

Checking an entire satellite fleet against thousands of pieces of debris is natively an $\mathcal{O}(N^2)$ operation [1]. Vyom-Sarathi projects the spatial environment into a K-Dimensional Tree (`scipy.spatial.cKDTree`). This reduces the volumetric proximity query to $\mathcal{O}(N \log N)$ complexity, allowing the system to instantly flag objects within a 500m Evasion Threshold and the critical 100m Collision Threshold [1].

3.2 Propulsion Physics

All maneuvers obey strict propulsion constraints [1]:

- **Dry Mass:** 500.0 kg [1]
- **Initial Propellant:** 50.0 kg [1]
- **Specific Impulse (I_{sp}):** 300.0 s [1]

Every maneuver instantly deducts the exact propellant mass consumed using the ideal Tsiolkovsky rocket equation [1]:

$$\Delta m = m_{current} \left(1 - e^{-\frac{|\Delta \vec{v}|}{I_{sp} \cdot g_0}} \right) \tag{3}$$

3.3 The Maneuver Lifecycle

1. **Phase 1 (Evasion):** If debris breaches the 500m threshold, the system calculates an aggressive 15 m/s maximum thrust limit [1] Transverse burn in the local RTN (Radial-Transverse-Normal) frame [1]. This alters the orbital phasing to safely dodge the debris, transforming the RTN vector back into the ECI frame to execute the burn [1].

2. **Phase 2 (Recovery):** The evasion burn inherently pushes the payload out of its nominal slot [1]. Once the threat passes and the mandatory 600-second thermal cooldown expires [1], the system calculates a 10 m/s geometric recovery vector to snap the satellite back into its assigned bounding box, optimizing Constellation Uptime [1].

3. **LOS Validation:** Maneuvers are rigorously validated against geometric Line-of-Sight (LOS) constraints [1]. Using Haversine mathematics and elevation mask angles, the system ensures the satellite has a direct, unobstructed radio link to one of the active Ground Stations [1] prior to burn execution.

4 Tactical Command Visualizer (Frontend)

The *Orbital Insight* dashboard is a browser-based UI built to mirror professional mission control software [1]. To maintain 60 FPS while drawing 10,000+ objects [1], standard DOM manipulation is bypassed in favor of GPU-accelerated HTML5 Canvas rendering [1].

- **Interactive Global Ground Track:** Utilizes a high-resolution topographical Earth raster image via an equirectangular projection. A custom virtual camera engine enables infinite panning and zooming. A Dynamic Debris Scalar solves the "Vanishing Pixel" problem, ensuring debris pixels dynamically scale dimensions at high magnification levels.

- **Conjunction Bullseye Radar:** A polar coordinate radar [1] dynamically anchors to selected satellites, rendering incoming debris across defined range rings [1].

- **Telemetry & Gantt Scheduler:** An automated Gantt chart plots historical and predicted thruster firings [1], visually rendering the mandatory 600-second cooldown blocks [1].

5 Deployment & Infrastructure

The software is containerized for deterministic deployment and automated grading. The highly optimized `Dockerfile` mandates the strict `ubuntu:22.04` base image to prevent dependency drift [1]. Layer caching is utilized for `requirements.txt` to drastically speed up rebuild times. Finally, the ASGI server strictly binds to `0.0.0.0:8000` [1], exposing the API for the high-frequency telemetry stress tests mandated by the hackathon harness.

6 Conclusion

Project VYOM-SARATHI bridges the gap between theoretical astrodynamics and scalable software engineering. By synthesizing JIT-compiled numerical integrators with advanced spatial

indexing algorithms and rigid architectural adherence, it provides a highly resilient blueprint for autonomous orbital management.
